Abstract The molecular clock is a fundamental tool for understanding the time and pace of evolution, requiring calibration information alongside molecular data. Sampling times are often used for calibration since some organisms accumulate enough mutations over the course of their sampling period. This practice ties together two key concepts: measurably evolving populations and the phylodynamic threshold. Our current understanding suggests that populations meeting these criteria are suitable for molecular clock calibration via sampling times. However, the definitions and implications of these concepts remain unclear. Using Hepatitis B virus-like simulations and analyses of empirical data, this study shows that determining whether a population is measurably evolving or has reached the phylodynamic threshold does not only depend on the data, but also on model assumptions and sampling strategies. In Bayesian applications, a lack of temporal signal due to a narrow sampling window results in a prior that is overly informative relative to the data, such that a prior that is potentially misleading typically requires a wider sampling window than one that is reasonable. In our analyses we demonstrate that assessing prior sensitivity is more important than the outcome of tests of temporal signal. Our results offer guidelines to improve molecular clock inferences and highlight limitations in molecular sequence sampling procedures.

Keywords: Measurably evolving population, phylodynamic threshold, molecular clock, Bayesian phylogenetics, microbial evolution.

1 Introduction

Molecular sequence data have become nearly ubiquitous for studying the evolution of modern and ancient organisms. A fundamental concept in molecular evolution is the ‘molecular clock’, which posits that substitutions accumulate roughly constantly over time (Zuckerkandl and Pauling, 1965). An underlying assumption of the classic molecular clock is that selective constraints are negligible for most sites and over time. The development of molecular clock models as statistical processes relaxes this and other assumptions by allowing for rate variation among branches (and sometimes sites see Ho 2014) in phylogenetic trees (reviewed by Guindon (2020), Ho and Duchêne (2014)).

39 Molecular clock models necessarily involve two key quantities, the evolutionary timescale and the ‘evolu-
40 tionary rate’, with the latter representing the combination of mutations and substitutions that accrue over
41 time. However, evolutionary times and rates are unidentifiable (Dos Reis and Yang (2013), as reviewed by
42 Bromham et al. 2018, Guindon 2020), and therefore cannot be jointly estimated using genetic sequence data
43 alone. To make inferences from genetic sequences, all molecular clock methods require prior assumption
44 about evolutionary times or rates, known as a ‘molecular clock calibration’. Three main calibrations exist:
45 First, the age of the most recent common ancestor between two samples can be constrained to a given time
46 point or interval (‘internal node calibration’). Second, a known estimate of the evolutionary rate can be in-
47 corporated (e.g. as a prior in Bayesian frameworks). Third, in cases where molecular sequences are sampled
48 at different points in time (heterochronous sampling), the tips of the phylogeny can be anchored to these
49 time points (‘tip calibration’; reviewed by Rieux and Balloux (2016)). The choice of calibration depends on
50 the information available and its reliability (Duchêne et al., 2014, Warnock et al., 2012). For instance, it
51 would be remiss to ignore evidence about when two lineages shared a common ancestor if the fossil record
52 is compelling (Gavryushkina et al., 2017, Ronquist et al., 2016). Crucially, multiple sources of calibration
53 information can be provided for the molecular clock.

54 1.1 Measurably evolving populations

55 Rapidly evolving organisms, notably many viruses and bacteria, have been found to accrue an appreciable
56 number of mutations over the sampling timescale. Influenza viruses, for example, have evolutionary rates
57 of around 6×10^{-3} subs/site/year (substitutions per genomic site per year) (Ghafari et al., 2022, Sanjuán,
58 2012). Assuming a genome size of 13,500 Kb, one would expect to observe one mutation every 4 to 5 days
59 ($\frac{365 \text{ days/year}}{13,500 \text{ sites} \times 6 \times 10^{-3} \text{ subs/site/year}} \approx 4.5 \text{ days/subs}$). If genome samples are collected over the course of a few
60 weeks, the sampling times themselves can be used to calibrate the molecular clock and tip calibration is
61 therefore warranted. Data sets for which tip calibration is feasible are considered to have been sampled from
62 a ‘measurably evolving population’ (Drummond et al., 2003b) and to have ‘temporal signal’.

63 Measurably evolving populations are typically characterised either by a sampling period that is long
64 relative to the evolutionary rate, a sufficiently big data set (long molecular sequences or many samples), or
65 both. Traditionally, such characteristics were mainly found in rapidly evolving organisms, typically RNA
66 viruses. Nowadays, advances in sequencing technologies have dramatically expanded the range of organisms
67 from which data sets can be considered to have been sampled from a measurably evolving population.
68 Namely, ancient DNA techniques have effectively expanded the genome sampling window for many organisms
69 (Duchene et al., 2020b, Spyrou et al., 2019a), and whole genome sequencing has meant that data sets of
70 ‘slowly’ evolving microbes often carry sufficient information for calibrating the molecular clock (Biek et al.,
71 2015) even when the sampling period covers only a few decades (Menardo et al., 2019).

72 1.2 The phylodynamic threshold

73 Genomic data sets collected during the early stages of an outbreak, for example, often pose two problems: low
74 genetic diversity and a narrow sampling window. Both can lead to highly uncertain estimates of evolutionary
75 rate and time of origin. The point at which an organism has accumulated sufficient genetic changes since its
76 emergence to allow for informative tip calibration is referred to as the ‘phylodynamic threshold’ (Duchene

77 et al., 2020a). At a minimum, tip calibration requires that one mutation has occurred over the sampling period
78 for the method to be informative. For a given organism, the minimum sampling period can be calculated as the
79 inverse of the product of genome size and the evolutionary rate (i.e. $\frac{1}{\text{genome size (sites)} \times \text{evol. rate(subs/site/year)}} =$
80 years to observe one mutation). We refer to this amount of time as the expected phylodynamic threshold.

81 The terms phylodynamic threshold and measurably evolving population are different, albeit related,
82 concepts. A population is measurably evolving if the samples available are sufficiently informative as to allow
83 for tip calibration. In contrast, the phylodynamic threshold is the amount of time over which we would
84 need to draw samples after their emergence for them to behave as from a measurably evolving population.
85 For a recently evolving pathogen the phylodynamic threshold would simply correspond to the time until it
86 can be considered a measurably evolving population, under the condition that the data have been collected
87 constantly over time. In contrast, an organism that emerged further in the past may have accumulated
88 considerable genetic diversity over time, effectively reaching its phylodynamic threshold. However, if samples
89 are drawn from a very short time window they may fail to capture a representative amount of such genetic
90 diversity.

91 1.3 Tests of temporal signal

92 Our ability to extract information from a tip calibration framework can be assessed through tests of temporal
93 signal. The importance of performing such tests arises from the observation that a lack of temporal signal
94 is associated with unreliable evolutionary rate estimates (Duchêne et al., 2015, Rieux and Balloux, 2016),
95 although the presence and direction of a potential bias remain poorly understood. However, it is important to
96 note that a lack of temporal signal does not necessarily preclude estimating evolutionary rates and timescales
97 because alternative sources of calibration, such as prior estimates of evolutionary rates or constraints on
98 internal node ages, can still be used to inform analyses.

99 In principle, frameworks developed to test for temporal signal do not differentiate between recently
100 emerging organisms (fig. 1a) and those with narrow sampling windows (fig. 1d), both of which may lack
101 temporal signal. As most of these tests involve fitting a phylogenetic model to the data, they implicitly
102 assume that the model adequately captures the evolutionary process and thus their performance also highly
103 depends on model fit. Recent research, for example, suggests that the choice of tree prior and molecular
104 clock model significantly impacts the sensitivity and specificity of temporal signal tests (Tay et al., 2024).
105 Thus, temporal signal is not solely a property of the data but also depends on the choice of model.

106 Various methods exist for assessing temporal signal. The root-to-tip regression (Buonagurio et al., 1986,
107 Drummond et al., 2003a, Gojobori et al., 1990) fits a regression to the distance from the root to the tips in a
108 phylogenetic tree against sampling time. High R^2 values of the regression suggest that phylogenetic distance
109 can be sensibly modelled as a linear function of time and can thus be used as an indication of informative
110 tip-calibration. Date-randomisation tests (Duchêne et al., 2015, Duchene et al., 2018, Ramsden et al., 2009,
111 Trovão et al., 2015) compare evolutionary rate estimates using correct sampling times against those from
112 permutations. Bayesian Evaluation of Temporal Signal (BETS; Duchene et al. (2020c)) evaluates whether
113 a model with sampling times performs better than a model that assumes isochronous sampling using Bayes
114 factors. Each method comes with a set of limitations and strengths, such that tests of temporal signal should
115 rather be used in combination than being mutually exclusive (Duchene et al., 2020c, Rieux and Balloux,

116 2016).

117 **1.4 Concepts of measurably evolving populations, the phylodynamic threshold, and**
118 **temporal signal in practice**

119 In fig. 1, we present four simple example cases to illustrate the relationships among the concepts of mea-
120 surably evolving populations, the phylodynamic threshold, and temporal signal. The first example depicts
121 an organism that has emerged recently and therefore has not yet reached its phylodynamic threshold (with
122 a phylogenetic time tree shown in panel (a)). Due to its recent origin, there has not been enough time for
123 the accumulation of a sufficient number of substitutions (represented in the phylogram in panel (b)), such
124 that it is not possible to establish a statistical relationship between molecular evolution (i.e., substitutions)
125 and time (as shown in panel (c)). A real-world example of such a case comes from the early phase of the
126 SARS-CoV-2 outbreak: initial efforts to estimate the evolutionary rate and time of origin had substantial
127 uncertainty due to a narrow sampling window and low genetic diversity (Boni et al., 2020). In Duchene et al.
128 (2020a), Bayesian phylodynamic analyses were conducted on genome data as the outbreak unfolded. The
129 number of available genomes and the width of the sampling window increased over time and ranged from
130 22 genomes sampled over 31 days to 122 genomes sampled over 63 days. Although early estimates of the
131 evolutionary rate and time of origin were highly uncertain, they quickly converged to stable values as more
132 data became available (Ghafari et al., 2022).

133 The second example in fig. 1 illustrates a case in which an organism has evolved over a long period,
134 but the available sequence data have been collected within a very narrow timeframe, insufficient to treat the
135 dataset as a measurably evolving population (time tree in panel (d) and phylogram in panel (e)). This results
136 in no temporal signal, as demonstrated by the lack of correlation in the root-to-tip regression in panel (f).
137 The causative agent of tuberculosis, the bacterium *Mycobacterium tuberculosis*, was commonly considered to
138 evolve too slowly for calibrating the molecular clock using samples collected over a few years Duchene et al.
139 (2016). A range of studies have shown, however, that for *M. tuberculosis* a genome sampling window of a few
140 decades might be sufficient for reliable clock calibration (Eldholm et al., 2015, Kühnert et al., 2018, Menardo
141 et al., 2019, Merker et al., 2022).

142 The third example in fig. 1 describes a data set that may involve a wide sampling window of time and
143 for which samples have been drawn from a population that has attained its phylodynamic threshold, but
144 with substantial rate variation among lineages – i.e. overdispersed molecular clock -, resulting in a lack of
145 temporal signal (panels (g) – (i)). This pattern appears to be the case in *Yersinia pestis*, the bacterium
146 that causes the plague, for which some localised outbreaks display obvious temporal signal, but its long-term
147 evolution has pervasive evolutionary rate variation (Andrades Valtueña et al., 2022, Eaton et al., 2023).

148 In the final example in fig. 1, a hypothetical organism has attained its phylodynamic threshold, has been
149 sampled for sufficiently long time, and evolutionary rate variation among lineages is low. These conditions
150 together produce a clear relationship between molecular evolution and time, thus providing unequivocal
151 temporal signal (panels (j) – (l)). The long term evolution of *Vibrio cholerae*, the causative agent of cholera,
152 and H3N2 influenza virus are exemplar microbes whose molecular evolution has been fairly constant across
153 long periods of time (Devault et al., 2014, Rambaut et al., 2016).

154 In summary, the concepts of measurably evolving population, phylodynamic threshold and temporal signal

155 describe the information that can be drawn from a sampled population about its evolutionary timescale.
156 Because populations that are not measurably evolving have been observed to yield biased estimates, they
157 remain important to consider (Gharbi et al., 2024). In Bayesian inference, such biases can be the result
158 of complex interactions between prior distributions or model settings that do not align with the true data
159 generating model, as these drive the inference in the absence of informative data. Traditionally, potential
160 biases due to prior interactions (Tay et al., 2024) or model misspecification (Möller et al., 2018) have been
161 found through simulations studies, while data analyses often involve little validations of the results (Mendes
162 et al., 2025). Here, we illustrate through a range of examples the degree to which differing levels of temporal
163 signal in a data set can interact with prior settings and model assumptions, both on simulated and empirical
164 data.

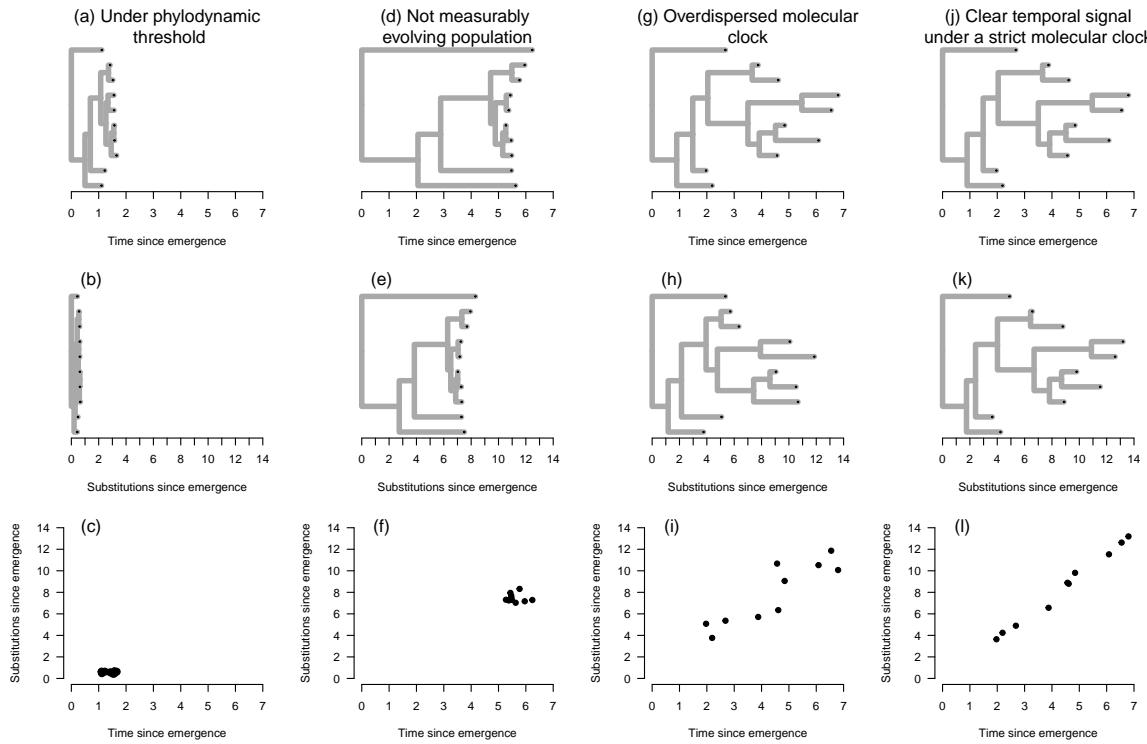

Figure 1: Examples of situations where temporal signal may or may not be detected. An organism that has not attained its phylodynamic threshold has a recent time of emergence (with a phylogenetic time tree shown in (a)) because it has not had sufficient time to accrue an appreciable number of substitutions (phylogenetic tree with branch lengths in subs/site, i.e. a ‘phylogram’, shown in (b)), such that it is not possible to establish a statistical relationship between molecular evolution (substitutions) and time (shown in (c)). Sequence data from an organism that has evolved for a substantial amount of time may have been sampled over a very narrow window of time that is not sufficient to treat it as a measurably evolving population (time tree in (d) and phylogram in (e)), which results in no temporal signal (root-to-tip regression in (f)). A data set may involve a wide sampling window of time and from a population that has attained its phylodynamic threshold, but an overdispersed molecular clock (substantial rate variation among lineages; panels (g) - (i)) may result in a lack of temporal signal. In (j) through (l) we show the situation where an organism has attained its phylodynamic threshold, it has been sampled for sufficiently long, and where evolutionary rate variation among lineages is negligible, as to produce a clear relationship between molecular evolution and time, and thus unequivocal temporal signal.

165 **2 Results**

166 We sought to pinpoint the impact of sampling strategies on molecular clock estimates. We focused our attention
167 on two major problems for emerging microbes and studies involving ancient DNA. First, we conducted
168 simulations varying the sampling window of a population that had attained its phylodynamic threshold. In
169 the second simulation scenario, we subsampled a population over time to vary the number of ancient samples,
170 leading to a temporal sampling bias. Finally, we illustrate these results in an empirical data set of Hepatitis
171 B virus (HBV) that includes a large number of ancient samples (Kocher et al., 2021). This virus has been
172 the subject of intense research due to its close association with human populations and complex evolutionary
173 dynamics (Kahila Bar-Gal et al., 2012, Paraskevis et al., 2013, Ross et al., 2018).

174 **2.1 Sampling windows relative to the phylodynamic threshold**

175 We simulated sequence data that resembled the evolution of HBV, a double-stranded DNA (dsDNA) virus
176 that has evolved in humans at least for around ten thousand years (Kocher et al., 2021). Our synthetic
177 data had a genome length of 3,200 nucleotides and an evolutionary rate of 1.5×10^{-5} subs/site/year
178 (Kocher et al., 2021, Mühlemann et al., 2018) with a moderate amount of rate variation among lineages
179 (see Materials and methods). Under these conditions we expect to observe one mutation every 20 years
180 ($\frac{1}{3,200 \text{ sites} \times 1.5 \times 10^{-5} \text{ subs/site/year}} \approx 20 \text{ years/subs}$). This number is important for the design of our simulation
181 experiments: 20 years is the expected phylodynamic threshold, as introduced above, and typically serves
182 as a good reference point from when on to expect temporal signal. We analysed the data under a Bayesian
183 phylogenetic framework and considered whether the posterior contained the true value used to generate the
184 data, known as coverage, and the width of the posterior, known as precision (a precise estimate has a narrow
185 posterior distribution).

186 We conceived a simulation process under which the evolutionary timescale had an expectation of ten
187 thousand years and with a sampling window of 0, 10, 20, 200 , or 2,000 years. A sampling window spanning
188 0 years results in ultrametric trees with the sampling times providing no calibration information. In contrast,
189 a sampling window of 10 years is half of the expected phylodynamic threshold and is likely to have weak
190 temporal signal (see fig. 1(d)-(f)). Sampling windows of 20 years (the expected phylodynamic threshold)
191 or wider are more likely to behave as measurably evolving populations with increasingly strong temporal
192 signal (see fig. 1(j)-(l)). Our synthetic data sets were analysed under Bayesian phylogenetic framework, as
193 implemented in the BEAST 2 platform (Bouckaert et al., 2019).

194 To investigate the impact of the prior we considered several configurations for the prior on the mean
195 evolutionary rate. In our analyses the molecular clock model is a uncorrelated relaxed molecular clock model
196 with an underlying lognormal distribution, with mean M . For this parameter we set nine possible prior
197 Gamma distributions, for which the prior mean could be the value used to generate the data, or one order of
198 magnitude higher or lower. We also included three degrees of uncertainty in this prior (see Fig 2 and table
199 2). In this respect, a prior with low uncertainty, and a mean that is much higher or lower than the true
200 should result in more bias than one that has higher uncertainty or is centred on the true value.

201 Our simulations for which the prior on M was centred on the true value had very high coverage. At least
202 94 out of 100 simulation replicates across sampling windows included the true value of M within their 95%

203 credible interval (CI) (table 1 and fig 2).

204 produced posterior estimates that included the correct value used to generate the data (i.e. 100% coverage;
205 fig. 2). Increasingly wide sampling windows improved the precision of the estimates, while still including
206 the correct value. This result is unsurprising, given our configuration of the prior. Here, the tree prior is a
207 constant-size coalescent for which the prior on the population size (known as θ) is an exponential distribution
208 with mean of 5,000, which matches the value used to generate the data. Similarly, the evolutionary rate had
209 a prior in the form of a Gamma distribution with *shape* = 1.5 and *rate* = 10^5 , whose mean is *shape/rate* =
210 1.5×10^{-5} and thus also matches the ‘true’ value. Although these priors are centred on the correct values,
211 they are vague, and it is important to note that in all cases, the posterior distributions of the evolutionary
212 rate and tree height were narrower than their priors, meaning that even in the absence of sampling times the
213 sequence data themselves provide some information about these two parameters.

Table 1: Coverage of the mean evolutionary rate, M . We consider coverage as whether a posterior distribution contains the value used to generate the data within its 95% credible interval (CI) and we show the number of simulation replicates out of 100 for which we found coverage. Data were simulated under trees with five possible sampling window depths relative to the phylodynamic threshold, where $Sw=\times D$ is for simulations with a sampling window of D times the phylodynamic threshold (20 years in our data; see fig 2). Each column is a sampling window depth, and the rows denote the configuration of the prior on the mean rate, M , for which we show the prior mean and the width of the 95% CI divided by the mean (larger values imply higher uncertainty). The true value of M is 1.5×10^{-5} subs/site/year.

Prior configuration (mean, 95%CI width)	Sw=0×	Sw=0.5×	Sw=1×	Sw=10×	Sw=100×
$1.5 \times 10^{-5}, 3.04$	100	100	100	96	95
$1.5 \times 10^{-5}, 6.33$	100	98	100	95	94
$1.5 \times 10^{-5}, 1.00$	100	100	100	94	94
$1.5 \times 10^{-4}, 3.04$	100	97	97	93	93
$1.5 \times 10^{-4}, 6.33$	100	99	100	94	92
$1.5 \times 10^{-4}, 1.00$	0	0	0	77	91
$1.5 \times 10^{-6}, 3.04$	0	0	0	68	91
$1.5 \times 10^{-6}, 6.33$	100	85	88	95	94
$1.5 \times 10^{-6}, 1.00$	0	0	0	0	1

214 **Revisions here**

215 We reanalysed these data with deliberately ‘misleading’ priors on the population size and the evolutionary
216 rate. The prior on the population size was an exponential distribution with mean of 50,000, whereas the
217 prior on the evolutionary rate was $Gamma(shape = 1.5, rate = 10^6)$ (mean= 1.5×10^{-6}). Under this
218 configuration the mean prior mass corresponds to trees that are one order of magnitude older than the
219 truth and evolutionary rates that are an order of magnitude slower. The objective of this experiment is
220 to determine whether the sampling window is sufficiently informative to overcome such misleading prior
221 information.

222 The posterior distribution was largely contained within the prior, resulting in low coverage for the evolution-
223 ary rate for sampling windows of 0, 10, and 20 years (0% coverage; fig. 3). A sampling window of

224 200 years was necessary to obtain 92% coverage, while a sampling window of 2,000 years had 100% coverage
225 and even higher precision (fig. 3). These results demonstrate that a misleading prior that places a very low
226 probability on the true value, requires a sampling window that is potentially much wider than the expected
227 phylodynamic threshold.

228 Contrary to the expectation that low temporal signal necessarily results in an underestimation of the
229 evolutionary rate and an overestimation of the tree height (Duchêne et al., 2015), we find that a lack of
230 temporal signal due to narrow sampling windows may simply lend more influence to the prior. To con-
231 firm this point we conducted an additional set of simulations where the mean evolutionary rate prior was
232 $\text{Gamma}(\text{shape} = 1.5, \text{rate} = 10^4)$ (mean= 1.5×10^{-4} , and 95% range from 1.1×10^{-5} to 4.7×10^{-4}), and
233 thus should lead to an overestimation of this parameter. As expected, we also found that increasing the
234 width of the sampling window resulted in a prior that was less influential on the posterior and with the latter
235 converging to the value used to generate the data (see Supplementary material). Compared to the previous
236 setting with incorrectly lower prior, a narrower sampling window already resulted in good coverage. This is
237 unsurprising, as higher rate values are less likely when only few mutations are observed in a relatively long
238 sampling window, while lower rate values cannot be excluded.

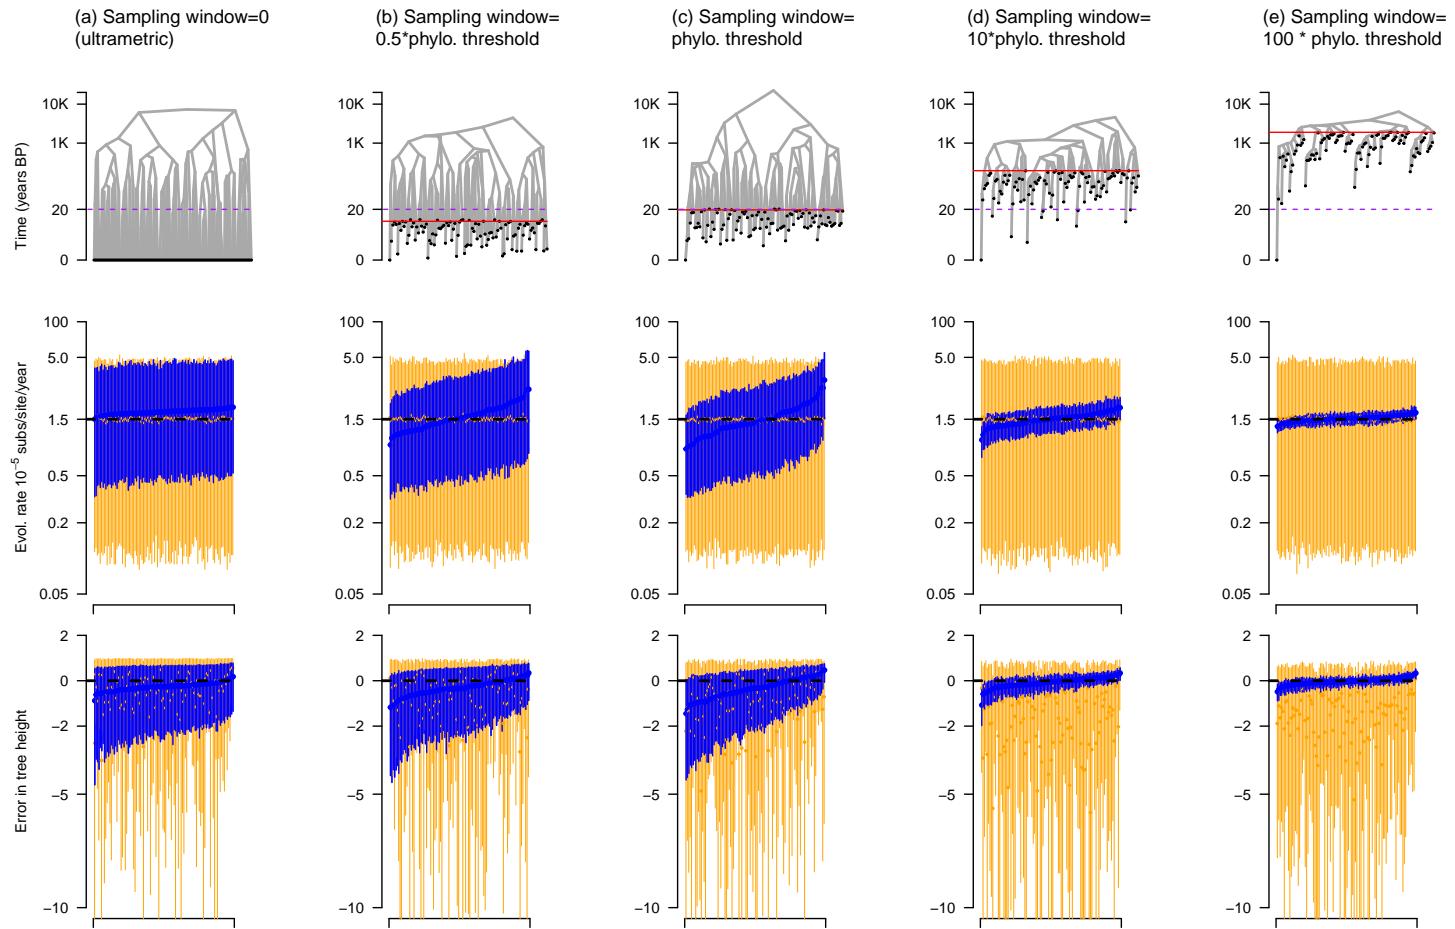

Figure 2: Simulations of varying sampling window widths. Each column corresponds to a simulation setting: (a) is for ultrametric trees where all samples are collected at the same point in time, (b) is for the situation where the sampling window is 10 years (half the expected phylodynamic threshold), (c) is where the sampling window is exactly the expected phylodynamic threshold of 20 years. Scenarios (d) and (e) denote sampling windows that are 10 and 100 times the expected phylodynamic threshold. The first row is an example of a simulated phylogenetic tree with branch lengths scaled in units of time. The black circles represent genomic samples. The purple dashed line is the expected phylodynamic threshold and the solid red line is for the oldest sample, such that it represents the sampling window. Note that time here is shown in \log_{10} scale. The second row is the estimated evolutionary rate over 100 simulations. The dashed black line is the value used to generate the data (i.e. the ground truth), the dark blue bars are the posterior, and those in orange are the prior. For the prior and the posterior we use solid circles to show the mean estimate and the width of the error bars denotes the 95% quantile range. The third row is the estimate of the error in tree height (the age of the tree). The error in tree height is calculated as $\frac{\text{true} - \text{estimated}}{\text{true}}$.

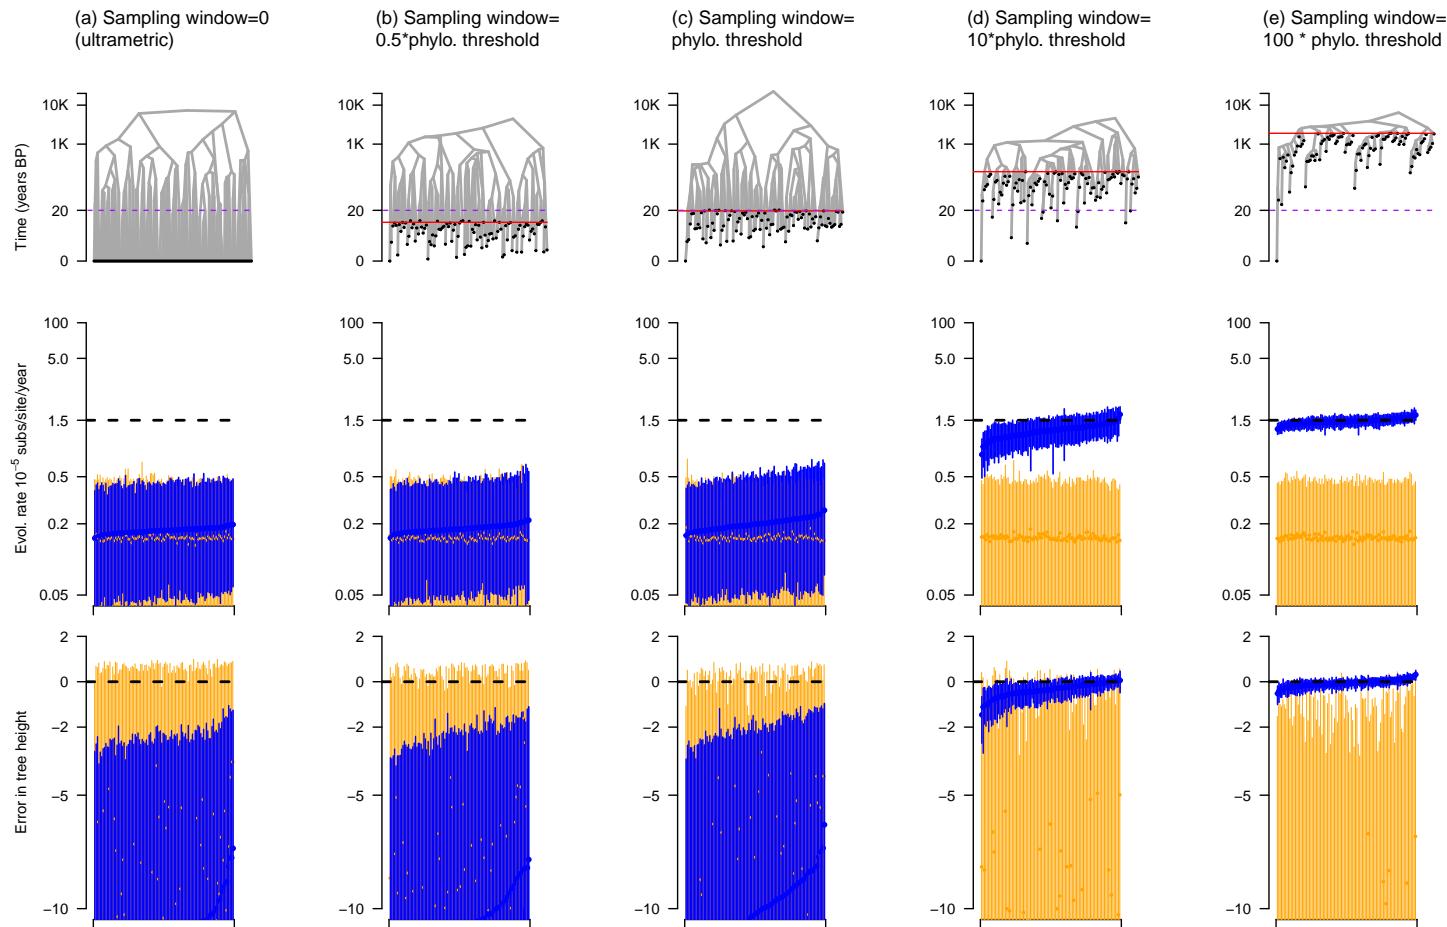

Figure 3: Simulations of varying sampling window widths. The colours, labels and legends match those from fig 2. However, in these analyses we deliberately use misleading priors on two key parameters, with an exponential distribution with mean 5,000 for the coalescent population size (true value=5,000), and a $\text{Gamma}(\text{shape} = 1.5, \text{rate} = 10^6)$ with mean= 1.5×10^{-6} (true value= 1.5×10^{-5}) for the mean evolutionary rate.

239 **2.2 Temporal sampling bias**

240 We investigated the impact of temporal sampling bias on the precision and accuracy of molecular clock
241 estimates. For this purpose we simulated data with the same genomic characteristics as HBV and where
242 genome sampling was conducted over five periods of time uniformly distributed between the present and the
243 root of the trees (fig. 4(a)). The fully sampled trees contained 500 genome samples, with 100 for each of
244 the five sampling times. Such stratified sampling is expected in ancient DNA studies, for example when a
245 set of samples are drawn from archaeological sites (e.g. Spyrou et al. (2019b)). We sampled the complete
246 data sets by randomly selecting 20 samples from each strata, which we refer to as ‘time-uniform’ sampling,
247 and by sampling with a probability that is inversely proportional to the age of the strata, referred to as
248 ‘time-biased’. The time-uniform and time-biased sampling strategies both contain 100 samples (1/5th of the
249 complete data), but the time-biased only includes a small number of ancient samples.

250 The coverage of the evolutionary rate estimate was comparable across simulation treatments, at 88% for
251 the complete data set, 83% for the time-uniform, and 89% for the time-biased (fig. 4(b)). The somewhat
252 higher coverage for the estimates from the time-biased analyses is likely because this sampling treatment has
253 the lowest precision in the posterior, rather than an improvement in both accuracy and precision.

254 We also calculated a measure of bias for both sampling strategies by counting the number of simulations
255 for which the posterior mean with either sampling strategy was higher than that with the complete data.
256 We found that 50% of the estimates under time-uniform sampling had higher means than the complete data,
257 while the same was true for 45% of those with time-biased sampling (fig. 5(a)). Although these numbers
258 do not indicate substantial bias, such as a systematic over- or underestimation, we do note that time-biased
259 sampling tends to produce lower mean evolutionary rate estimates than those obtained from the complete
260 data or time-uniform sampling.

261 The most striking result of the temporal sampling strategies was in the precision of the posterior. Both
262 sampling treatments resulted in posterior distributions that were wider than with the complete data, which is
263 to be expected because they are effectively smaller data sets with less information. However, the time-biased
264 sampling data sets almost invariably have posterior distributions that were less precise than those from the
265 time-uniform sampling (Fig. 5(b)), implying that the distribution of samples, and not just the number, is
266 important for estimation precision.

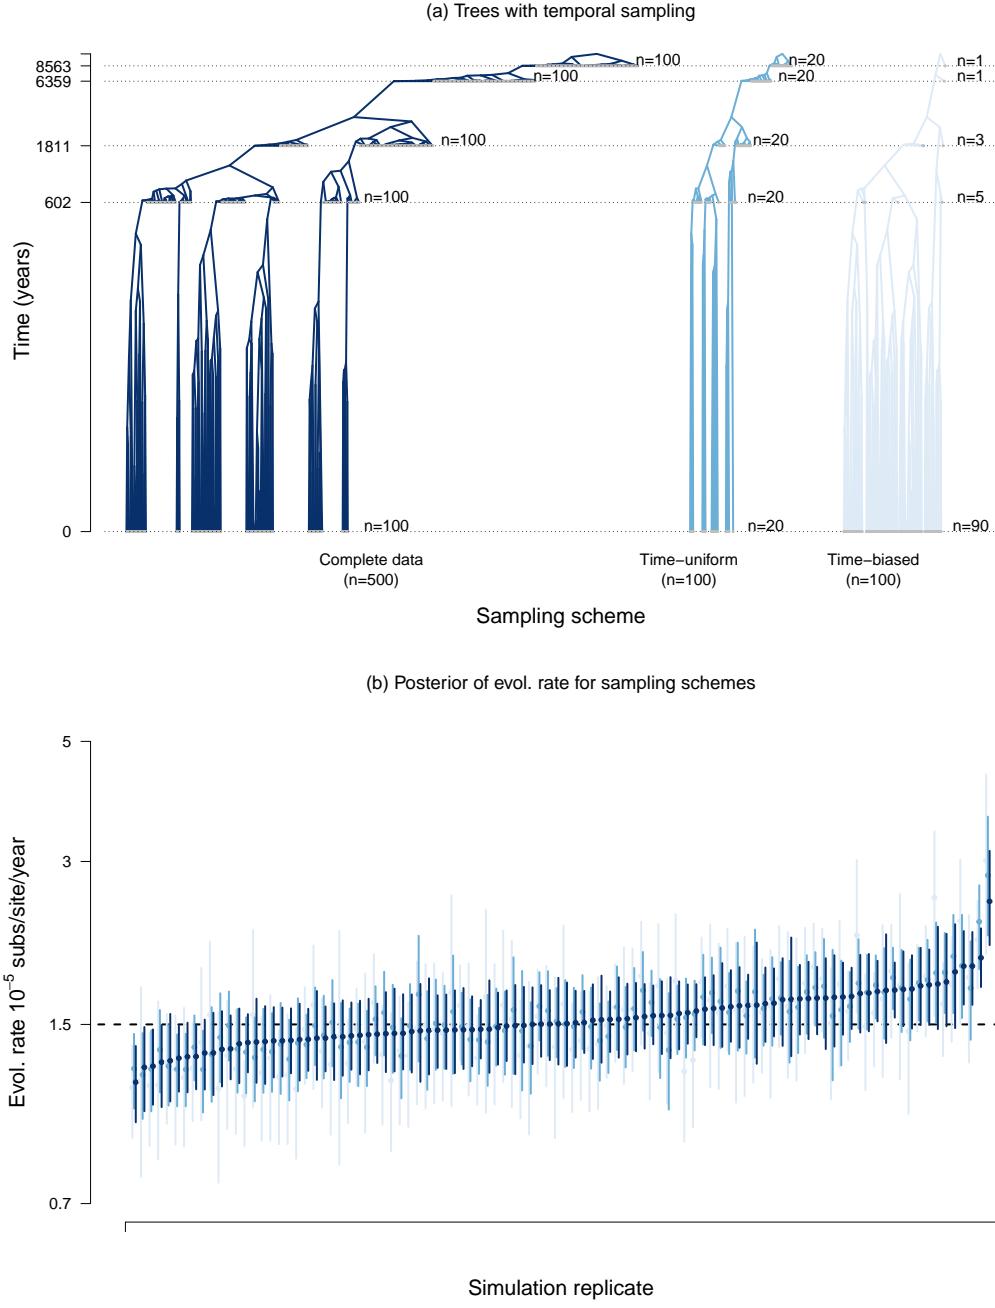

Figure 4: Analyses under sampling treatments over time. In (a) we show an example of the trees for a simulation replicate, with branch lengths and time in \log_{10} scale. The complete data set consists of 500 genome samples, collected in five points in time, with an equal number of samples per time point ($n=100$). The first sampling strategy is unbiased, where 20 samples are drawn from each time point, and is known here as ‘time-uniform’. The ‘time-biased’ regime is where sampling intensity decreases over time. Note that the total number of samples in the time-uniform and time-biased treatments is identical. In (b) we show the posterior estimates of the evolutionary rate for each treatment. Each simulation replicate is represented by three error bars: dark blue for the complete data, and lighter shades of blue for the estimates from the time-uniform and time-biased sampling treatments. The width of the error bars denotes the 95% quantile range and the dots are the mean value. The dashed line shows the true value used to generate the data.

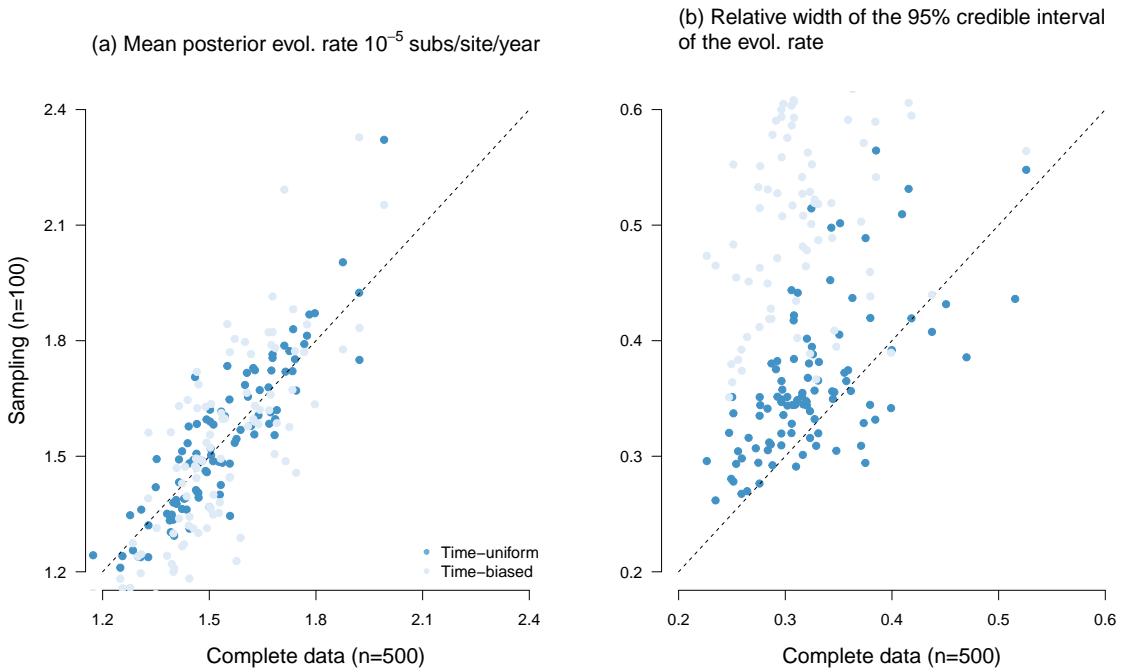

Figure 5: Comparison of posterior evolutionary rate estimates between complete data (x-axis) and two sampling treatments (y-axis): time-uniform (dark blue) and time-biased (light blue). Each dot is a simulation replicate. In (a) we show the mean posterior evolutionary rate estimate. Points that fall along the $y=x$ line (dashed line) represent identical mean posterior for the sampling treatment and the complete data, while those above or below represent higher or lower estimates, respectively, relative to the complete data. In (b) we show the width of the credible interval (a measure of precision or uncertainty), calculated as the upper minus the lower 95% credible interval range divided by the mean value. Values that fall along the $y=x$ line denote those for which the complete data and either sampling strategies are equally precise, while those above and below the $y=x$ line are more or less precise, respectively.

267 2.3 Empirical analyses of Hepatitis B virus (HBV) ancient and modern genomes

268 To explore the impact of the width of the sampling window and the temporal sampling bias on the estimates
 269 of evolutionary rates and times, we performed analyses of a HBV data set that includes modern and ancient
 270 genomes, from Kocher et al. (2021). The complete data set consisted of 232 genomes of length 3,344 nu-
 271 cleotides and with a sampling window of 10,535 years. HBV is an ancient pathogen that has likely codiverged
 272 with human populations for thousands of years (Locarnini et al., 2021, Mühlmann et al., 2018, Paraskevis
 273 et al., 2013, Zehender et al., 2014), and thus its phylodynamic threshold has been reached while it has not
 274 been empirically established if it can be considered to be a measurably evolving population, as is the case
 275 for recent outbreaks, like SARS-CoV-2 (Duchene et al., 2020a).

276 For our first set of analyses we varied the width of the sampling window. We drew 100 genomes with
 277 different sampling window widths: 0 (only modern samples), up to 500, 1,000, or 5,000 years before present.
 278 Increasing the sampling window resulted in estimates of the evolutionary rate that were more precise and
 279 closer to the estimate from the complete data set (fig. 6). Here we find that the evolutionary rate is estimated
 280 to be higher for shorter sampling windows, with correspondingly older estimates for the tree height (see

281 Supplementary material). This pattern can be due to one or a combination of other factors influencing the
 282 inference, for example the vagaries of evolutionary rate variation in this virus, particularly time-dependency
 283 (Vrancken et al., 2017). Similarly, population structure that is unaccounted for has been shown to produce
 284 an overestimation of the evolutionary rate, because under the tree prior samples that are genetically linked
 285 are expected to have been sampled at the same point in time (Möller et al., 2018).

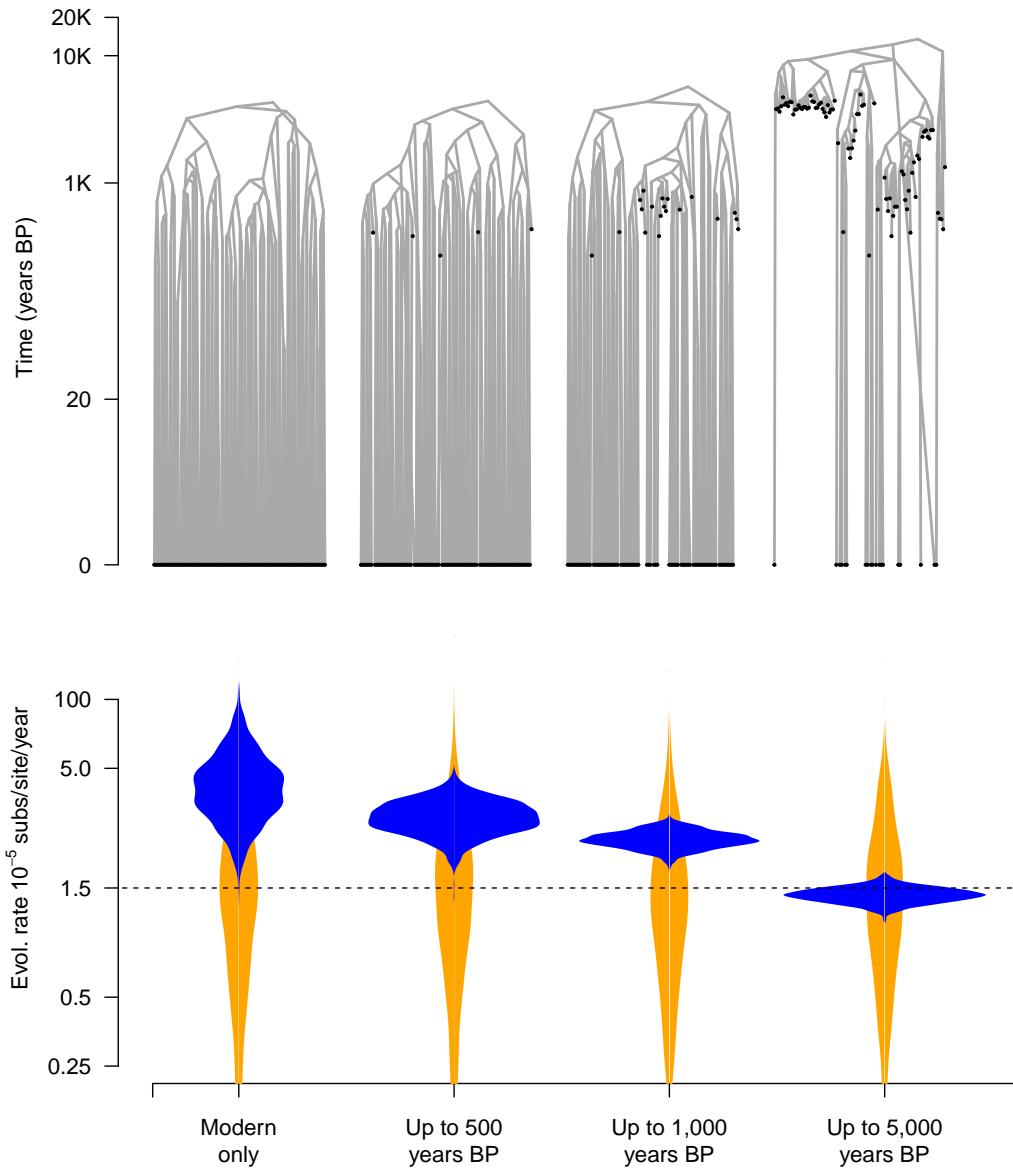

Figure 6: Results from empirical analyses of Hepatitis B virus (HBV) ancient DNA data. The phylogenetic trees correspond to highest clade credibility trees from three analyses where the data were subsampled to increase the width of the sampling window progressively. First, we only consider modern samples, then those up to 500, 1,000, and 5,000 years before present. In all cases the data sets consist of 100 genome samples. The violin plots show the posterior distribution of the evolutionary rate in blue and its corresponding prior in orange. The dashed line shows the mean evolutionary rate estimate from the complete data set.

286 For our second set of empirical analyses, we subsampled the data to produce a range of temporally biased
287 sampling scenarios. We varied the proportion of modern samples, from 95% to 10%. Here the sampling
288 window is constant because we always retain the most ancient samples. Each data set consisted of 100
289 genomes, such that they only differ in the distribution of modern and ancient samples (fig. 7).

290 The impact of temporal sampling bias was less clear than in our simulations above (figs 4 and 5). The data
291 set with 95% modern genomes had the highest uncertainty in the evolutionary rate estimate, but uncertainty
292 did not decrease monotonically with the proportion of modern genomes. Moreover, the posterior estimate of
293 the evolutionary rate from the data set with 50% modern genomes deviated the most from the that obtained
294 using the full data set. Critically, when we analysed these data using the ‘misleading’ prior setting we
295 found that increasing the number of ancient samples resulted in a less influential prior (see Supplementary
296 material). These results demonstrate that the exact impact of temporal sampling bias may be difficult to
297 predict in practice, but that generally increasing the number of ancient samples results in data sets that are
298 more informative, in that the difference between the prior and posterior is more pronounced than when only
299 a few ancient samples are available.

300 3 Discussion

301 The concepts of the phyloydamic threshold, measurably evolving populations, and temporal signal are
302 helpful for our understanding of rapidly evolving organisms or data sets with ancient DNA. Our analyses
303 help us disentangle the definition of these concepts and their practical implications.

304 The phylodynamic threshold and measurable evolution are not discrete bounds. Increasing the sampling
305 window generally improves precision and accuracy, but there is no clear cut-off for when the estimates become
306 accurate and objectively ‘precise’.

307 Notably, the prior on the phylogenetic tree and the evolutionary rate are particularly influential for
308 estimating evolutionary rates and timescales (for a detailed investigation see Tay et al. (2024)). In our
309 simulations with a reasonable prior the posterior always included the correct value, but when we set a
310 misleading prior a sampling window of 10 times the time expected to accrue one mutation (i.e. the so called
311 expected phylodynamic threshold) was necessary to obtain a posterior that included the correct value. As a
312 consequence, the phylodynamic threshold and measurable evolution depend on the extent to which the data
313 inform the posterior, which is ultimately a measure of the relative contribution of the prior and the data (via
314 the likelihood function).

315 Ideally, the prior and posterior of key parameters, particularly the height of the root node should overlap,
316 while the posterior should be narrower than the prior (i.e. more informative), meaning that the data and
317 the prior are not in conflict (for recent work on quantifying prior-data conflict see: Nott et al. 2020). In this
318 vein, assessing the adequacy of the model and prior via predictive checks can be illuminating (McElreath,
319 2018), particularly in situations where the joint prior is poorly understood (see Baele and Lemey 2014,
320 Wang and Yang 2014 for discussions about the prior in Bayesian phylogenetics). Recent years have seen the
321 development of a range of methods for assessing phylogenetic model adequacy (Brown and Thomson, 2018,
322 Duchêne et al., 2018, Duchene et al., 2019, McElreath, 2018), for instance one can simulate phylogenetic trees
323 under the posterior estimates to verify whether the height of the root node and the topology could have been

324 generated by the model in question.

325 Measurably evolving populations are those for which the phylodynamic threshold has been attained and
326 the sampling window is *sufficiently* wide. The criteria for determining the phylodynamic threshold and
327 whether a population is measurably evolving are the same, and are typically assessed via temporal signal.
328 Statistical tests for this purpose quantify the strength of the association between sampling times and genetic
329 distance (Duchêne et al., 2015, Featherstone et al., 2024, Murray et al., 2016, Rambaut et al., 2016, Rieux
330 and Balloux, 2016). That is, the degree to which the sampling times on their own constitute an informative
331 molecular clock calibration. We contend that assessing prior sensitivity is more important than the outcome
332 of tests of temporal signal for obtaining reliable molecular clock estimates. In fact, a poor choice of prior
333 can mislead tests of temporal signal (Tay et al., 2024). If data are drawn from a sampling window that
334 spans the expected phylodynamic threshold, the presence of temporal signal is likely supported by most
335 tests, suggesting accurate estimates. Yet, if the prior used for the estimation is misleading and informative,
336 it might actually obscure the ‘correct’ signal from the data. In contrast, if the data are drawn from a narrow
337 sampling window but the prior is reasonable then the estimates may be still be reliable, despite a lack of
338 temporal signal. It also has to be noted that an increasing sampling effort does not necessarily lead to
339 increasingly correct inferences, because misspecification not only in prior distributions of hyper-parameters,
340 but also in the underlying model, can introduce bias (Ferretti et al., 2024, Möller et al., 2018).

341 An obvious concern about molecular clock calibrations using sequence sampling times is sampling bias.
342 We find that temporal sampling bias, where data are overwhelmingly collected at a particular period of
343 time does not have a substantial impact in estimation accuracy on a simple coalescent model, but that
344 increasing the number of ancient sequences can improve precision. An other form of sampling bias is when
345 genetic diversity is not uniformly sampled or the underlying population is structured. Previous work has
346 demonstrated that in such cases, the evolutionary rate and the age of the root node tend to be overestimated
347 (Möller et al., 2018), a problem that diminishes when sequence data are increasingly informative or by
348 using a tree prior that explicitly models population structure (e.g. Kühnert et al. 2016, Müller et al. 2017).

349 Our study has a few limitations that have been partly addressed elsewhere. The number of sequences
350 is fixed in most of our experiments, but it is well known that increasing the number of sequences generally
351 means that data are more informative and thus the estimates are more precise (see Möller et al. (2018) and
352 our fig. 4), and therefore it is likely that the width of the sampling window needed to obtain reliable estimates
353 also depends on the number of sequences. Moreover, our simulation experiments involved a low degree of
354 evolutionary rate variation among lineages. In this respect, it is expected that the width of the sampling
355 window scales with the amount of dispersion in the molecular clock. In addition, our simulations are based
356 on a simple population dynamic model, the constant coalescent. The impact of the sampling scheme and
357 width is likely to be more complex for models with more parameters. We also assume the correct model of
358 evolution and population growth in all simulation-based inferences. With the empirical analysis, we, however,
359 highlight how conclusions drawn from these do not directly extend to real-world data. Rather, the isolated
360 effects found therein describe only one of many elements impacting the inference from real data. Further
361 scrutiny of these factors is warranted, but the main implication is that the necessary sampling time window
362 is combination of the data set, the organism, and the model at hand.

363 Overall, our study elucidates some of the fundamental intricacies of molecular clock calibration strategies.

364 We urge researchers to carefully question their model and its underlying prior assumptions, not only via tests
 365 of temporal signal, but also through careful choice of the prior, an understanding of the information content
 366 in the data, and the implications of model misspecification.

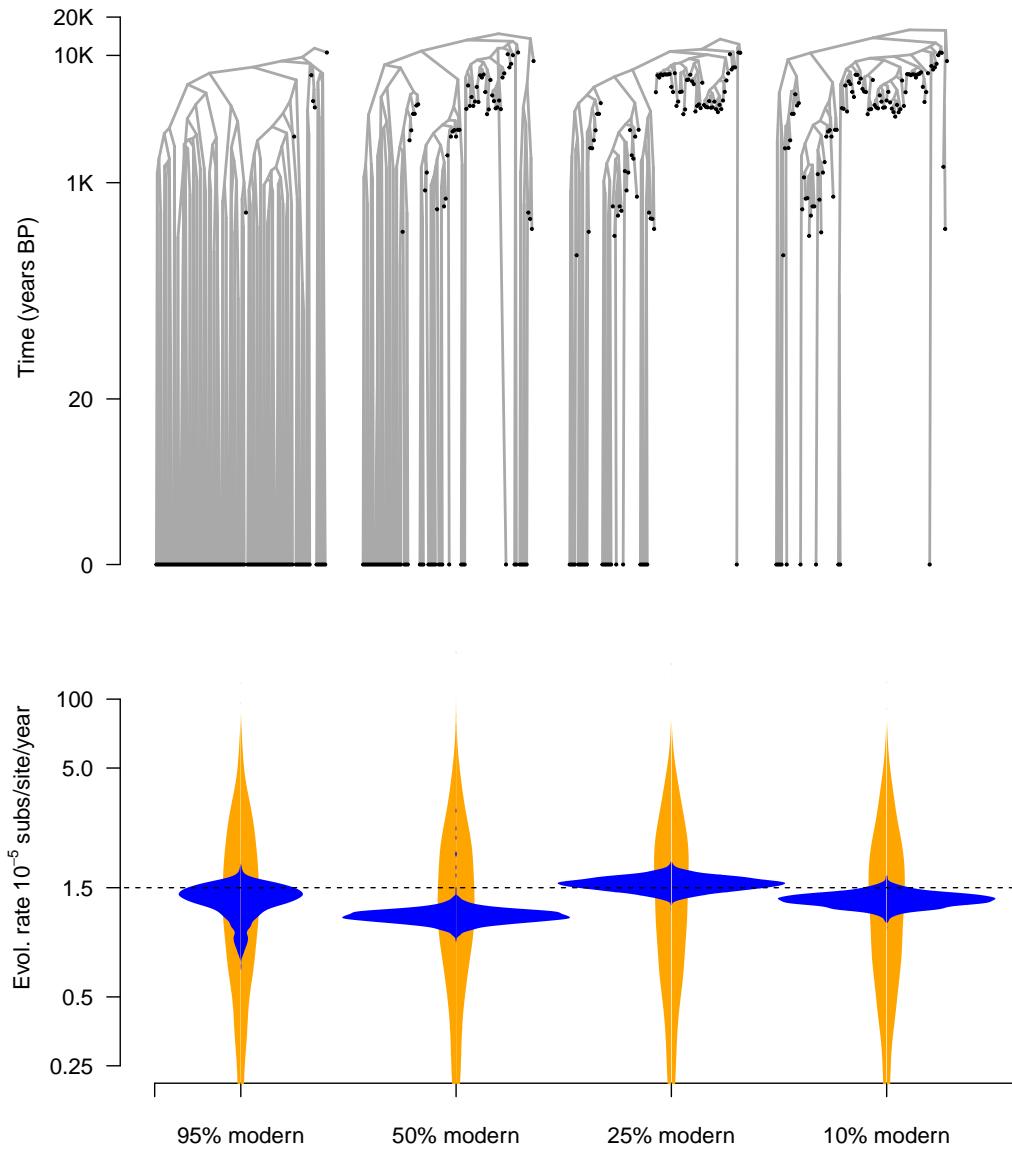

Figure 7: Results from empirical analyses of Hepatitis B virus (HBV) ancient DNA data. The phylogenetic trees correspond to highest clade credibility trees from three analyses where the data were subsampled to include an increasing number of ancient samples. First, we consider a data set for which the samples are 95% modern and the remaining 5% being the most ancient. Then, we reduce the number of modern samples to 50%, 25% and 10%, and the rest being ancient. Note that the sampling window is constant because we always retain the most ancient samples. In all cases the data sets consist of 100 genome samples. The violin plots show the posterior distribution of the evolutionary rate in blue and its corresponding prior in orange. The dashed line shows the mean evolutionary rate estimate from the complete data set.

367 **4 Materials and methods**

368 **4.1 Simulations**

369 **4.1.1 Data generation**

370 We simulated phylogenetic trees and the evolution of nucleotide sequences to assess the impact of varying
371 the sampling window and temporal sampling bias. We parameterised our simulations to resemble an HBV
372 population evolving over 10,000 years before present, as described by Kocher et al. (2021).

373 We generated phylogenetic trees under a coalescent process in which the population size has been constant
374 over time using the package ReMaster (Vaughan, 2024), part of the BEAST 2 (version 2.7) software. We set
375 the population size to 5,000, which results in trees with an average age of about 10,000 time units (years).
376 The number of samples (i.e. tips) drawn from the trees and their ages was defined in ReMaster, according
377 to the simulation scenario described below.

378 The simulation of sequence data requires trees with branch lengths in units of subs/site, instead of time.
379 For this purpose, we multiplied the branch lengths of the simulated time tree with the rate of evolution,
380 a lognormally distributed random variable with parameters $\mu = \log(1.5 \times 10^{-5}) - \frac{0.25^2}{2}$ and $\sigma = 0.25$.
381 This procedure equates to simulating an uncorrelated relaxed molecular clock model with an underlying
382 lognormal distribution (Drummond et al., 2006) with mean, M of 1.5×10^{-5} subs/site/year and a standard
383 deviation of 0.25 subs/site/year (following that $\mu = \log(M) - \frac{\sigma^2}{2}$). Because we multiply the branch lengths
384 in units of years by a variable in subs/site/year, the resulting trees have branch lengths in units of subs/site,
385 formally known as phylogenograms, in contrast to chronograms where the branch lengths correspond to time.
386 We obtained sequence alignments using the R package phangorn (v2.8.1) (Schliep, 2011), according to a
387 HKY+ Γ_4 substitution model, with parameters $\kappa = 2$, $\alpha = 4$, and equal base frequencies. The alignments
388 consisted of 3,200 nucleotides to match the average genome size of HBV.

389 We considered the expected phylodynamic threshold of our data to be about 20 years. For our simulations
390 where we varied the sampling window, we set the ages of 100 tips to be sampled at present (all have an age
391 of 0), or to be drawn from a uniform distribution between 0 and 10 (1/2 of the expected phylodynamic
392 threshold), 0 and 20, 0 and 200, or 0 and 2,000.

393 To investigate the impact of temporal sampling bias we initially simulated trees with 500 tips with
394 sampling times distributed in 5 time points, with 100 tips per time point. The distribution of sampling times
395 followed an exponential distribution with mean of 4,000, such that sampling times were concentrated towards
396 the present. We simulated these complete trees in ReMaster. We followed the procedure above to simulate
397 a molecular clock model and sequence alignments.

398 We conducted two sampling schemes for the trees with 500 tips: the ‘time-uniform’ scheme consisted
399 of drawing 20 samples from each time point, whereas the ‘time-biased’ scheme included of mostly modern
400 samples (90 from the present, and 5, 3, 1, and 1 from the remaining time points). For each simulation
401 scenario we generated 100 replicates.

402 4.1.2 Analysis of simulated data

403 We analysed all data sets in BEAST 2 under a model that matched that used to generate the data: the
 404 HKY+ Γ_4 substitution model, a uncorrelated relaxed molecular clock model with an underlying lognormal
 405 distribution, and a constant size coalescent tree prior. We used the default prior configuration in the program,
 406 except for the mean evolutionary rate (M) and the population size of the coalescent (θ). For the population
 407 size we assumed $\theta \sim \text{Exponential}(\text{mean} = 5,000)$, which is centred in the value used to generate the data.
 408 The expected height of the root node is roughly 10,000 years (expected time to coalescent = $2 \times \theta$ for an
 409 ultrametric tree, see Nordborg (2019)).

410 For the mean evolutionary rate we considered a range of priors with different degrees of information
 411 content (uncertainty) and for which the mean was either the value used to generate the data, or one order of
 412 magnitude higher or lower, as shown in table 2. We also included three degrees of uncertainty in such prior
 413 distributions, where the 95% quantile width was equal to the mean, or around three or six times as wide. In
 414 all cases we set the sampling times for calibration. In the case of ultrametric trees, sampling times are set to
 415 the present, such that all calibration information is provided by the prior.

Table 2: Prior configuration for the mean evolutionary rate, M of the lognormal distribution of branch rates. Note that the mean of the *Gamma* distribution here is *shape/rate* and that the true value used to generate the data is 1.5×10^{-5} subs/site/year.

Mean value of M	Prior configuration	95% quantile width / mean M
1.5×10^{-5}	$\text{Gamma}(\text{shape} = 1.5, \text{rate} = 1 \times 10^5)$	3.04
1.5×10^{-5}	$\text{Gamma}(\text{shape} = 0.3, \text{rate} = 2 \times 10^4)$	6.33
1.5×10^{-5}	$\text{Gamma}(\text{shape} = 15, \text{rate} = 1 \times 10^6)$	1.00
1.5×10^{-4}	$\text{Gamma}(\text{shape} = 1.5, \text{rate} = 1 \times 10^4)$	3.04
1.5×10^{-4}	$\text{Gamma}(\text{shape} = 0.3, \text{rate} = 2 \times 10^3)$	6.33
1.5×10^{-4}	$\text{Gamma}(\text{shape} = 15, \text{rate} = 1 \times 10^5)$	1.00
1.5×10^{-6}	$\text{Gamma}(\text{shape} = 1.5, \text{rate} = 1 \times 10^6)$	3.04
1.5×10^{-6}	$\text{Gamma}(\text{shape} = 0.3, \text{rate} = 2 \times 10^5)$	6.33
1.5×10^{-6}	$\text{Gamma}(\text{shape} = 15, \text{rate} = 1 \times 10^7)$	1.00

416 We used Markov chain Monte Carlo (MCMC) to sample the posterior distribution. We set the chain
 417 length to 10^8 steps, sampling every 5×10^4 steps. We deemed sufficient sampling by verifying that the
 418 effective sample size was at least 200, by using the R package CODA (version 0.19) (Plummer et al., 2006).
 419 When this criterion was not met we extended the chain length to 5×10^8 steps.

420 Our simulations with varying sampling window width used two possible prior configurations. To assess
 421 their impact we drew MCMC samples from the marginal prior of the evolutionary rate and the height of the
 422 root node. That is, the prior for a given parameter integrating over the prior in other parameters, the number
 423 of tips, and their heights. We obtained such samples by setting the option `sampleFromPrior="true"` in the
 424 input xml files in BEAST 2, which conducts the MCMC while ignoring the phylogenetic likelihood.

425 **4.1.3 HBV empirical data**

426 We selected a complete genome data set of HBV published by Kocher et al. (2021). The complete alignment
427 included 232 genomes of length 3,344 nucleotides, with 1,807 variable sites, and 1,498 site patterns. The
428 sampling times ranged from the present to 10,535 years before present. To investigate the impact of varying
429 the sampling window and on temporal sampling bias we subsampled the data as described in our Results
430 section. We analysed each data set using the same model and prior settings as in our simulations, including
431 the use of the reasonable and misleading prior configuration.

432 **5 Data availability**

433 Computer code, analysis files, and data sets in this study are available at:
